# 5. SITES 102-103-104 – BLAKE-BAHAMA OUTER RIDGE (NORTHERN END)

The Shipboard Scientific Party<sup>1</sup>

# INTRODUCTION

Geophysicists studying the deep-sea area off the Blake Plateau during the late 1950's concluded that the Blake-Bahama Outer Ridge is a foundered chain of islands and reefs structurally connected to the Cape Fear Arch off the Carolinas, (Hersey *et al.*, 1959). During the early 1960's scientists of the Lamont--Doherty Geological Observatory made continuous seismic reflection profiles over the ridge and showed that it is a vast accumulation of sediments lying on a horizontal reflecting surface (Layer A) which in turn lies above the rough acoustic basement reflector (Ewing and Ewing, 1964). This discovery led to a number of concepts attempting to explain the processes of formation of such huge sediment bodies in the deep sea.

Ewing *et al.* (1966) suggested that much of the material forming the ridge had been eroded from the Blake Plateau by the Gulf Stream. Andrews (1967) suggested that the ridge was formed by an enormous slump from a proximal up-slope position, in this case from the Blake Plateau region.

Heezen and Hollister (1964) and Heezen *et al.* (1966) proposed that the ridge, as well as many other fine-grained sediment bodies in the deep sea, owes its shape and structure to the effects of mud-carrying, contour-following deep currents ("contour currents") associated with deep thermohaline circulation.

Bryan (1970) and Markl *et al.* (1970) combined these concepts, suggesting that interaction of turbid flow from the Blake Plateau with the southward-flowing contour current initiated the development of the ridge which subsequently was enlarged and perhaps somewhat reshaped by further deposition and erosion associated with the contour currents.

The Blake-Bahama Outer Ridge (Figure 1) includes deposits of several shapes and sizes, from dunes a few kilometers long and tens of meters in height, to ridges many hundreds of kilometers long and thousands of meters high (Markl *et al.*, 1970).

The principal objective of Sites 102, 103 and 104 was to determine the geologic history of the Blake-Bahama Outer Ridge by investigating its structure, composition, rate of growth, and the provenance of constituent sediments.

## **OPERATIONS**

The ship arrived at Site 102 on the crest of the Blake-Bahama Outer Ridge during the late hours of April 30, and drilling was commenced at 1120 hours on May 1. A light-set diamond bit was chosen for this hole. The bottom hole assembly was the same as that used for most of the holes of this leg, consisting mainly of bit and outer core barrel, eight drill collars, and three bumper subs.

The sediment was soft and penetration progressed smoothly for the first three cores. Drill string rotation and pumping were required below a depth of 100 meters, but there was no difficulty in penetration until a depth of about 620 meters was reached. At this depth, which correlates well with the prominent conformable reflector at 0.62 second below bottom in the profiler record (Figure 2a), the sediment became much firmer and drier, and penetration slowed severely. After more than twelve hours drilling in this zone with a penetration rate of only 3 m/hr, the hole was abandoned. There had been some speculation that the bit might have clogged or the seals were blown out of a bumper sub, rather than that the sediment caused difficult penetration; but when the string was recovered no equipment problem was found. Therefore, the sharp decrease in penetration rate must indicate a significant change in lithology at the depth of the prominent seismic reflector at 0.62 second. By comparing the data from this hole and Hole 103 (Figure 2b), it is obvious that the reflector is not a time boundary and, therefore, must result from diagenetic processes.

Most of the cores at this site contained substantial amounts of organic material and were gassy, usually partially extruding themselves from the plastic liners and creating gaps in the remaining sections. Chromatograph measurements indicate that the gas is principally methane with only a small fraction (usually less than 0.5 per cent) of ethane.

Hole 103 was drilled on the southwest flank of the Blake-Bahama Outer Ridge at a location where seismic

Figure 1. Bathymetry of the Blake-Bahama Outer Ridge system (after Mankl, et al, 1970). Track segments locate seismic profiler sections shown in Figures 2a, 2b and 2c.

Figure 2a. Vema 21 Seismic profiler section across the Blake-Bahama Outer Ridge, (crestal region expanded below). See Figure 1 for location.

profiler data indicated an outcropping of the deeper beds penetrated in Hole 102 (Figure 2b). Drilling commenced at 1400 hours on 5 May, 1970. The second core, taken at a subbottom depth of 40 meters, brought up late Miocene sediment which had not been reached in the crest hole until a depth of more than 500 meters.

After the difficulty experienced at Hole 102 in drilling the firmer sediment with the diamond bit, a drag bit was chosen to drill this hole. It appeared to perform well, and during the drilled interval above the deepest core, penetrated firm clay at a good rate. Unfortunately, after Core 7 was taken the hole began to show signs of serious collapse and had to be abandoned.

The sediment samples were very similar to those at Hole 102, consisting mainly of silty clay with appreciable amounts of organic material. All of the cores contained a substantial amount of gas, consisting primarily of methane with a trace of ethane.

After the collapse of Hole 103, enough time remained for about 36 hours more drilling, and a decision was made to drill a third hole (Hole 104) on the northeast flank of the ridge (Figure 2c) at approximately the same water depth as Hole 103, drilled on the southwest flank. Drilling commenced at 1400 hours on 7 May, 1970, in a water depth of 3821 meters. The 3-cone carbide button roller bit used for Hole 99A was employed again.

After only 3 or 4 meters of penetration, several hard, apparently thin beds were encountered, requiring bit rotation and a substantial amount of weight. The hard material, some of which was recovered in Core 1, appears as a finely laminated calcite "crust" covered with calcite-filled burrow-like structures.

Figure 2b. Lithology and seismic stratigraphy at Site 102 (right) and Site 103 (left).

Most of the cored section consisted of hemipelagic silty mud similar to that found in Holes 102 and 103. The deepest core, taken at a depth corresponding to that of the prominent conformable reflector at 0.62 second (Figure 2c) contained approximately 15 centimeters of very hard ankerite. This layer or nodule required several minutes to drill through and was as hard drilling as any of the cherts, limestones, or basalts cored in previous holes during this leg. The material underneath the ankerite appeared to be little different from that above it. Unfortunately, time had run out at this point, and drilling was terminated in order for the ship to make its scheduled arrival at Norfolk.

The situation with respect to gas in the sediments was about the same as at Holes 102 and 103. The chromatograph showed only a trace of ethane. The first three cores of Hole 104 had a strong odor of hydrogen sulfide ( $H_2S$ ), but this diminished rapidly in the deeper part of the section.

## STRATIGRAPHY

### **Biostratigraphy**

Assemblages of abundant calcareous nannoplankton, planktonic foraminifera, dinoflagellates, Radiolaria,

and diatoms of Holocene to early middle Miocene age were encountered at these sites. Approximately 600 meters of middle Miocene, 300 meters of late Miocene, 350 meters of Pliocene and 220 meters of Pleistocene sediments are present.

The foraminiferal and nannoplankton assemblages contain the same tropical/subtropical components that have been observed in worldwide equatorial latitudes. They correspond well with the biostratigraphic zones established by Blow (1969), Martini and Worsley (1970), and the nannofossil zonation of Milow used on Leg 9. The composite section of Sites 102, 103 and 104 contains each of Zones N. 23 to N. 10/9 as defined by Blow (1969).

Two major stratigraphic boundaries (according to foraminiferal data) are documented; the Miocene-Pliocene in Core 2 at Site 103, and Pliocene-Pleistocene in Core 8 at Site 102. In addition, three major unconformities are present; one at Site 104 (Core 1), and two at Site 103 (within Core 1).

Pollen grains and spores occur in all the examined samples. Pleistocene grains consist mainly of pine,

Figure 2c. Lithology and seismic stratigraphy at Site 104.

scattered spruce and pteridophyte spores, which suggests transportation from a northerly source. Reworked grains of Cretaceous and Carboniferous ages are also present. In the upper and middle Miocene sediments, the pollen assemblages are more varied, containing appreciable amounts of oak pollen, grasses, sedges, alder and hickory; this suggests either a climate warmer than the Pleistocene in the same northerly direction, or increased stream discharge and marine currents, or change in source area. Reworked grains of Cretaceous age are also more common, some with excellent preservation, which suggests possible contributions from the Atlantic Coastal Plain or deep-sea deposits. The foraminifers offer little evidence with regard to source of sediment, except that some sublittoral forms are usually minor constituents of the foraminiferal assemblages. This indicates displacement from shallow water.

### Foraminifera

Refer to the chapter titled "Neogene Foraminiferal Biostratigraphy" for a detailed analysis of the plank-tonic foraminiferal assemblages at Sites 102, 103 and 104.

#### Calcareous Nannoplankton

Coring at Site 102 recovered sediment ranging in age from late Miocene to Quaternary. The first core, from 9 meters, contained a typical Pleistocene nannoplankton assemblage. The second core, from 27 meters, is also Pleistocene and represents perhaps a glacial interval judging from the common to abundant concentration of large specimens of *Coccolithus pelagicus*, a species that has a definite cold-water preference in modern oceans. Cores 3 to 8 were likewise assigned to the Quaternary. The core catcher of Core 9 contains a few specimens of *Discoaster brouweri* and thus, was, assigned to the latest Pliocene N. 21 Zone of Blow. Core 10 contains an assemblage indicative of the lower part of N. 21. Core 12 was placed within Zone N. 20. Cores 13, 14 and 15 were assigned to the early Pliocene Zone N. 19, and Core 16 to either very low in Zone N. 19 or possibly to the upper part of Zone N. 18. Cores 17, 18 and 19 were considered to be late Miocene, Zone N. 18.

Coring at Site 103 recovered sediments ranging in age from Holocene at the sea floor to middle Miocene at a depth of 449 meters. Core 1 extends from the surface to a depth of 8 meters, and the bottom of the core contains an early Pliocene assemblage. In superposed sequence, Cores 2 through 7 recovered nannoplankton assemblages of late Miocene in Core 2 to middle Miocene in Core 7. In all but the lower two cores, nannoplankton are present in abundance and are well preserved. Core 6 contains only a few forms, and in Core 7 they are very rare. In these two cores solution effects are commonly observed on the foraminifera.

Cores from Site 104 recovered sediments as young as Quaternary at the top and as old as earliest middle Miocene at a depth of 617 meters. The top of the first core contains a Quaternary assemblage, but the sample from the core catcher was assigned to the late Miocene (probably Zone N. 17 of Blow). The remaining cores (2 through 10) revealed a gradual increase in age through the middle Miocene, terminating in the earliest middle Miocene *Sphenolithus heteromorphus* Zone (N. 9/10).

### Dinoflagellates

Dinoflagellate cysts were recovered from all samples examined at Site 102. Operculodinium centrocarpum (Deflandre and Cookson), Tectatodinium pellitum Wall, and species of Spiniferites are common in the Quaternary assemblages of Cores 1 through 6. Achomosphaera ramulifera (Deflandre) occurs in the Pliocene cores, in addition to those species found also in the Quaternary. At Site 103, Hystrichosphaeropsis obscurum new species was found in the cores of Miocene age. The Miocene cores contain a diversified assemblage of pollen grains, including those assigned to oak, hickory, Compositae and grasses. Reworked grains are scattered through the samples, including those of Cretaceous and Carboniferous ages.

*Hystrichosphaeropsis obscurum* occurs in the Miocene cores of Site 104. *Pentadinium taeniagerum* Gerlach occurs in Core 10 at Site 104.

# **Rate of Sediment Accumulation**

During late Miocene time, sediment at Site 102 accumulated at a rate of 2.5 cm/1000 yr. and increased to 13.7 cm/1000 yr. during the Pleistocene.

At Site 103 approximately 200 meters of late middle and early late Miocene sediment accumulated at a rate of 19.3 cm/1000 yr., and continued at this rate to the end of the Miocene. Rates through the early and middle Pliocene were about 2.6 cm/1000 yr.

At Site 104 middle Miocene sediments accumulated at a rate (19.5 cm/1000 yr.) similar to that calculated for the late middle and early late Miocene at Site 103. During the remainder of late Miocene time, a considerable drop in sedimentation rate (1.8 cm/1000 yr.) occurred at Site 104. In other words, during the late middle and early late Miocene the rate of accumulation at Site 103 (west flank of ridge) was approximately twice that at Site 104 (east flank of ridge). This suggests perhaps that the greatest amount of sediment was being supplied to the southwestern portion of the ridge during late Miocene time.

### Lithology

At Sites 102, 103 and 104-on the crest (3425 meters), southwest flank (3964 meters) and northeast flank (3811 meters), respectively, of the Blake-Bahama Outer Ridge-a total of 1727 meters of dark greenishgray hemipelagic silty mud was penetrated; 192 meters of this material were recovered in 36 cores. Sediment age ranges from middle Miocene to Holocene. All three sites have in common the late Miocene foraminiferal biostratigraphic Zone N. 17 as well as correlatable sediment types as determined by smear slide analysis. They will be treated together as one sequence representing the uppermost kilometer of ridge crest sediment.

Three main variations in the hemipelagic sediments are distinguished (1) siliceous, calcareous, and heavy mineral-rich Pleistocene sediments deposited at a rate of about 14 cm/1000 yr., (2) non-siliceous, siderite-pyrite-glauconite-rich Pliocene and late Miocene sediments deposited at a rate of about 9 cm/1000 yr., (3) siliceous, noncalcareous, siderite-rich middle Miocene sediments deposited at a rate of about 19 cm/1000 yr.

#### Pleistocene Sediments (N. 22 - N. 23)

Approximately 220 meters of the Pleistocene was penetrated at Site 102; 72 meters of this were cored and 52 meters were recovered. The accumulation rate of almost 14 cm/1000 yr. is extremely high for a deep-sea environment, which is rarely over 5 cm/1000 yr. Less than 5 meters of the surface cores at Sites 103 and 104 were Pleistocene and, thus, the following discussion deals entirely with material recovered in Cores 1 through 8 at Site 102.

The upper 10 meters of sediment at Site 102 resemble the sediment recovered in piston cores taken on the crest of the Blake-Bahama Outer Ridge by Lamont-Doherty scientists (Heezen *et al.*, 1966). The upper half meter is Holocene yellow-brown and gray, laminated, silty, foraminiferal ooze. Smear slide examinations reveal an abundance of clay minerals, inorganic silt-sized detritus and organic debris, foraminifera and coccoliths, aragonite needles, and a flood of radiolarians, diatoms, and sponge spicules. Siliceous microfossils are almost totally lacking in the underlying Pliocene sediment. The abundant inorganic detrital silt laminae contain abundant heavy minerals.

Below the first few meters, the color becomes dark gray to grayish-brown; black patches of iron sulfide become quite abundant. Methane gas with traces of ethane becomes detectable below about 10 meters below bottom. Below a depth of about 100 meters, a few layers of rose-gray and mottled yellow-green silty clay occur. Siderite, dolomite and aragonite are found sporadically, and burrows are often filled with inorganic light-colored quartz silt.

A few hard, well-indurated crusts of limy mud containing cemented wormlike burrows and burrow-fillings were found at Site 104. Rather large fragments of hard lithographic limestone were found immediately below the crust. The lower limit of the fragments coincides with a major unconformity that separates the early Pleistocene from the late Miocene. Similar crusty surfaces have been found in modern sediments where strong bottom currents scour the sea floor thereby temporarily preventing deposition. It is the absence of Pliocene sediments at Site 104 which indicates recent periods of scouring or nondeposition on the east flank of the Blake-Bahama Outer Ridge.

### Pliocene-Late Miocene Sediment (N. 21 - N. 15)

At Sites 102, 103 and 104, a total of 687 meters of Pliocene (N. 18/19 - N 21) to late Miocene (N. 14/15) sediment was penetrated; 83 meters of this was recovered in 18 cores. This late Miocene sediment is very similar to the Pliocene material and thus the two will be treated as one lithologic unit. It is homogeneous, dark greenish-gray, silty hemipelagic mud, occasionally mottled with lighter olive-gray hues.

The distinction between Pleistocene and Pliocene-late Miocene sediments lies in minor mineralogic differences revealed by smear-slide analysis and an abundance of siliceous material. Within the Pleistocene, siderite, pyrite and glauconite make their first consistent appearance. They increase in amount with depth in the section. Many of the burrows are found to be filled with siderite silt. Aragonite needles and heavy minerals, common in the Pleistocene, become rare to absent in the older sediment. In the Pleistocene deposits radiolarians, sponge spicules and diatoms are very abundant, whereas in the Pliocene-late Miocene they are rare. A significant change in mineralogy and palynology also occurs near the boundary between the late Miocene and middle Miocene. This boundary, penetrated at Sites 103 and 104, was not reached at Site 102 and thus the following discussion is based on smear slides obtained from these two correlatable sites.

### Middle Miocene Sediment (N. 14 - N. 9)

A change at the late-middle Miocene boundary is a gradual decrease in abundance of heavy minerals. Foraminiferal tests and nannoplankton are almost totally lacking in smear slides of middle Miocene sediment. However, their decrease has been rather gradual since about middle Pliocene, and may reflect progressive dissolution of carbonate as a function of time and/or depth of burial. At the bottom of the oldest sediment recovered (Core 10, Site 104, Zone N. 10/9), a bed or nodule of ankerite was cored.

Below the middle Miocene-late Miocene boundary an increase in abundance of siliceous organisms occurs. Also, near this boundary an abrupt change in pollen and spore assemblages is noted. Pleistocene and Pliocene sediment contains spruce and fir pollen that appears to have been transported from northerly sources, whereas the middle Miocene sediment contains more temperate forms such as alder, hickory, oak, grasses and sedges that may have been derived from more proximal sources and thus have a more restricted transportational history.

### DISCUSSION AND CONCLUSIONS

Cores recovered from these sites can be correlated on the basis of one common biostratigraphic zone (N. 17) as well as on the basis of similar sediment composition. Zone N. 16 is present in Holes 102 and 103. The nature of the sediments and the attitude of reflectors recorded on seismic reflection profiles (Markl et al., 1970) suggest that at least the upper 600 meters of the northern end of the Blake-Bahama Outer Ridge is a large accumulation of rapidly-deposited, hemipelagic, silty carbonaceous clay of Pliocene-Pleistocene age that has been transported to this region from the north by southerly-flowing bottom currents. Erosion has occurred along both flanks of the ridge. The underlying 600 meters of late and middle Miocene hemipelagic sediment recovered at Site 104 appear to have been derived from nearer sources. The upper 150 meters of sediment recovered at Site 102 appears to have been deposited as a conformable lens of Pleistocene hemipelagic silty clay on top of the Pliocene and middle Miocene accumulations.

The western flank of the ridge in the vicinity of Site 103 represents a continuation of the straight, east-west oriented slope running from the vicinity of "Nose" of the Blake Plateau to the ridge crest at approximately  $30^{\circ} 30'$  N. The unconformities apparent in the seismic profile near Site 103 must be related to the same processes that have formed this east-west linear slope. The unconformities and disturbed reflectors seen in profiles over the eastern flank of the Blake-Bahama Outer Ridge in the vicinity of Site 104 indicate erosion.

As discussed in a previous chapter, the Tertiary sediments at Site 101 at the southern end of the Blake-Bahama Outer Ridge have been transported from the north by southerly-flowing currents and, subsequently, penecontemporaneously sculpted and shaped by the Western Boundary Undercurrent (Heezen, Hollister and Ruddiman, 1966).

At Hole 102, the drilling-rate graph shows only one important break – that at a depth of 620 meters. In the appropriate region of the seismic record, there is only one reflector that could reasonably correlate with the drilling break; that is, the one at 0.62 second which is conformable to the topography and appears to cut across bedding planes. Such a correlation indicates an average sound velocity of 2.0 km/sec in the upper 600 meters of section. It is possible to divide the section into two layers and compute average velocities of 1.9 and 2.3 km/sec, respectively—as shown in the drilling-rate graph (Figure 3).

Drilling at Hole 103 did not achieve sufficient penetration to permit a velocity determination to be made.

At Hole 104, penetration was made at a uniform rate down to 615 meters where a very hard layer, or nodule, of ankerite was cored. Unfortunately, there was not enough time to drill deeper, so we cannot be certain whether the ankerite was an isolated nodule or part of an ankerite-rich zone. In any case, this drilling break is the only observed event to correlate with the reflector at 0.61 second. The correlation indicates an average sound velocity of 2.16 km/sec for the upper 600 meters, a value rather close to that computed for the section at Hole 102.

A sound velocity greater than 2 km/sec seems to be somewhat high for the hemipelagic mud cored at these sites, particularly when we consider that most of the material contained significant amounts of methane. However, if we assume a lower velocity for this material, we are faced with having to accept the fact that we drilled through the prominent reflector without noticing it and then encountered a significant drilling break underneath the reflector. This may indicate that it is the homogeneous zone beneath the reflector that resisted drilling, and the reflectivity of the zone just above it is due to factors not apparent in the normal examination of the cores.

Alternatively, we can accept the interval velocity of about 2 km/sec as a valid measurement and attribute the rather high velocity to the presence of the methane. Stoll et al. (1971) have pointed out that under usual deep sea conditions, the pressure and temperature in the uppermost few hundred meters of sediment are such that methane would exist as a hydrate-an ice-like substance. They further made laboratory measurements in which the speed of sound in water-saturated sand was observed to increase from about 1.7 km/sec to more than 2.5 km/sec after methane had been bubbled through the sample for several hours at 2° to 3° C and 800 to 1000 psi pressure. Although this may account for the abnormal sound velocity, this is not an obvious explanation of the reflector itself. The fact that it is so conformable to the sea floor and cuts across time lines ranging from mid-Miocene to Quaternary suggests that it is caused by a diagenetic process with a short time constant. It seems reasonable to assume that temperature would change much more rapidly than pressure with increasing depth in the sediment, so the diagenesis appears to have a strong tendency to follow an isotherm and, therefore, may be directly or indirectly related to the presence of gas.
