ABSTRACT

The magnetic properties of fresh, upper Miocene sediment samples from DSDP Hole 521A are dominated by magnetite. Alternating magnetic field (AF) demagnetization reveals a stable remanent magnetization component but is unable to reduce it to zero. Thermal demagnetization of samples that have been dehydrated isolates a well-defined stable component, but the procedure becomes ineffective at high temperature, probably because of alteration of the magnetic mineralogy. A combination of AF and thermal cleaning was employed to define the magnetic stratigraphy for this hole. Correlation of the magnetic polarity zonation with the magnetic time scale derived from oceanic magnetic anomalies was aided by nannofossil zonations. Normal polarity of the basal sediments agrees with the site position on Anomaly 5C. Tentative identifications of magnetozones that correspond to Anomalies 5, 5A, and 5B can also be made; above this level the magnetic stratigraphy does not have sufficient character to permit correlations. The sedimentation rate calculated from the magnetic zonation is very low, averaging 2.0 m/m.y.; close to the bottom of the hole the rate is about 7 m/m.y. The magnetozone identified with Anomaly 5 is found in association with nannofossil zones NN9/NN10.

INTRODUCTION

Magnetic stratigraphy studies in continental exposures of pelagic limestones have confirmed the geomagnetic polarity sequence derived from oceanic magnetic anomalies for the Late Cretaceous and Paleogene (Lowrie and Alvarez, 1977; Lowrie et al., 1982; Napoleone et al., 1983). A new magnetic polarity time scale for this time (Lowrie and Alvarez, 1981) was prepared by a three-stage process: (1) the positions of 12 key biostratigraphic stage boundaries in these sections were correlated with the reversal sequence, (2) the best available age estimates were associated with these calibration levels, and (3) the ages of intervening reversal boundaries were dated by linear interpolation between calibration levels. When this new time scale was used, the age of the bottom sediment in Paleogene and Late Cretaceous DSDP sites was found to agree well with the age associated with the anomaly on which the hole was drilled (Lowrie and Alvarez, 1981, fig. 4). This agreement indicates that the magnetic time scale and the biostratigraphic ages are well correlated for this period of time. In the Neogene, however, there are large discrepancies, mainly because direct magnetostratigraphic correlations of the oceanic magnetic polarity record have not yet been carried out for the entire period.

The correlation of the Neogene magnetic and biostratigraphic records was attempted by Ryan et al. (1974). The method used to achieve the correlation was unavoidably circuitous and indirect because of the absence of suitable paleomagnetic stratigraphy results. Magnetic zonation of deep-sea sediment cores gave a good match with the polarity sequence in radiometrically dated lavas and extended the correlation with the oceanic reversal sequence into the late Pliocene (Opdyke, 1972), but the application of this method to older sediments depended on finding surface hiatuses on the ocean bottom and piecing together the polarity sequences from overlapping core segments. Theyer and Hammond (1974) used this method to obtain coverage for most of the Neogene. Continental magnetic stratigraphy studies in Pakistan have recently permitted the correlation of early Pliocene and late Miocene polarity zonations with the oceanic record (Tauxe and Opdyke, in press).

Many early studies of the magnetic stratigraphy of sediments drilled from DSDP sites were plagued by magnetic disturbance and incomplete core recovery. The first of these problems appears to have been overcome with the introduction of the hydraulic piston corer. The second problem has been partially solved by using this device, but incomplete recovery continues to leave hiatuses in the DSDP magnetic record and reduces the reliability of correlations with the oceanic magnetic anomaly polarity sequence. Successful magnetostratigraphic correlation also depends on the presence of distinctive patterns in the polarity sequence. If the reversal rate is high or if the sequence has no special identifying characteristics, it is not possible to make an unequivocal correlation. All these problems contribute to the difficulty of interpreting the Miocene magnetostratigraphy at DSDP Hole 521A.

SAMPLING AND MEASUREMENT

Fresh sediment samples were taken at the Lamont-Doherty Geological Observatory Core Repository with the aid of a special device.
developed by Dr. N. Petersen. This device is equivalent to a miniature piston corer and gives well-oriented, small cylindrical samples (volume 3.3 cm$^3$) of the soft sediment. These samples were extruded directly into close-fitting, cylindrical plastic containers that had a ridged inner surface to prevent any sample rotation and that were tightly capped to reduce dehydration. When some of the cylinders were opened several weeks later, few of the samples were found to have shrunk appreciably. About 37 m of core were sampled at intervals of 7 to 10 cm and gave 324 samples for this study.

The remanent magnetizations were measured with a three-axis cryogenic magnetometer interfaced with a Hewlett-Packard 1000 mini-computer. Each component was sampled 10 times in each measurement position; the three components were measured in each of three measurement positions. A small cubic holder was used to hold the plastic cylinder containing the sample. The reliability of each measurement was controlled by determining the angular dispersion of the repeated measurements. The above procedure gave excellent results; the dispersion was generally only a few degrees and often less than 1°.

**MAGNETIC PROPERTIES**

An indication of the magnetic mineralogy of the samples was obtained by observing the acquisition of isothermal remanent magnetization (IRM) in 33 selected samples. Dunlop (1972) has shown that this procedure reveals the complete coercivity spectrum of the sample and that this can be diagnostic of the magnetic mineral. Typical IRM acquisition in DSDP Hole 521A samples is illustrated in Figure 1. In progressively stronger fields the IRM increases sharply at first, reaching a value near to saturation IRM in fields of less than 0.2 T. In stronger fields most samples show little significant further increase of IRM; the remanence of these samples is carried virtually exclusively by a low-coercivity magnetic mineral, probably magnetite. The IRM curves of some samples show a slight but definite increase up to about 0.8 T; in these samples the low-coercivity (magnetite) component also dominates the coercivity spectrum, but a minor hard component is also present.

The stability of the remanence was investigated in two suites of 10 pilot samples. These samples were distributed at approximately equal intervals along the core. One suite was progressively demagnetized in alternating magnetic fields that were increased stepwise up to a maximum of 60 mT. A small unstable component was usually present at first, but it was easily removed in a peak field of 5 to 10 mT. Above this step the remanent magnetization was demagnetized in a uniform fashion. Vector plots indicate the presence of a single component that decays smoothly but does not reach the origin in peak magnetic fields of 40 mT (Fig. 2). In stronger demagnetizing fields the remanence signal became erratic, most likely as the result of the addition of spurious components.

The second suite of samples was progressively demagnetized thermally. The samples were removed from their plastic cylinders; the marks left by the holder ridges enabled accurate re-orientation for later measurement. Before the first heating steps, the samples were wrapped in aluminum foil and dried at room temperature in nitrogen gas in the field-free space within mu-metal shields. The low-field magnetic susceptibility was measured before and after dehydration and showed no change that might be indicative of chemical alteration. The remanence often underwent major changes in intensity; the direction was affected to a lesser degree. It appeared to make no difference whether the samples were dehydrated in an inert atmosphere or in air. Thermal demagnetization of the dehydrated samples removed an unstable component below 200°C and defined a vector at higher temperatures that demagnetized fairly linearly toward the origin of a vector diagram (Fig. 3). The remanence in some samples demagnetized noisily at high temperature, indicating possible alteration of the magnetic mineralogy. The susceptibility was measured after each heating step. It increased gently and continuously in all samples up to 500°C (Fig. 4). Over this temperature range the magnetic mineralogy appeared to be fairly stable thermodynamically and exhibited no sudden increase indicative of generation of a new magnetite phase, as has been reported during the thermal treatment of pelagic limestones (Lowrie and Heller, 1982).

Thermal demagnetization was on the whole more effective in cleaning the sediment remanences than AF demagnetization. Thermal cleaning was also effective in samples that had been previously AF demagnetized (Fig. 5). Although AF cleaning usually resulted in the correct polarity, the stable final direction was often reached only after additional thermal demagnetization.

On the basis of these pilot studies the main collection was AF demagnetized in peak fields of 10, 20, 30, and 40 mT. Where this treatment did not produce a satisfactory cleaned direction, the sample was further demagnetized thermally.

---

**Figure 1.** Acquisition of IRM ($M_{0}$ = maximum value of IRM = 1.93 Am$^{-1}$) in a typical late Miocene sediment sample from Hole 521A (Sample 521A-10-2, 5 cm). ($\Delta M/\Delta B$)/$M_{0}$ is the coercivity spectrum of the sample; it shows that most of the ferromagnetic fraction is in the coercivity range below 0.15 T and probably corresponds to detrital magnetite.
The intensity of natural remanent magnetization (NRM) was consistent between 0.001 and 0.01 A/m but showed several systematic fluctuations down the core (Fig. 6). The intensity variations were matched by corresponding changes in magnetic susceptibility, which indicates that the controlling factor was the core lithology (in particular, the ferromagnetic and paramagnetic minerals) and not the depositional field intensity. The remanent intensity shows more scatter than the susceptibility, possibly because of the presence of low-coercivity components.

The definition of the magnetic polarity stratigraphy in Hole 521A was quite variable. Below about 60 m sub-bottom the reversal stratigraphy was clearly defined, even in undemagnetized samples (Fig. 6). From 48 to 60 m sub-bottom, normal and reversed magnetozones were unequivocally present in stratigraphic plots of the magnetically cleaned, characteristic remanent magnetization (ChRM), but they presented a more ragged appearance. The upper part of the core (above 45 m sub-bottom) consisted largely of shallow, more scattered inclinations, and only a feeble zonation was possible on the basis of AF-demagnetized directions alone. The combination of AF and thermal cleaning led to a distinct
improvement in the magnetic polarity zonation as determined from the ChRM inclinations (Fig. 7).

The samples were not oriented azimuthally relative to geographic coordinates. However, core continuity was often very good within individual, 1.5-m-long core sections. Therefore, the ChRM directions were averaged (Fisher, 1953) to get the mean direction for each section; the declination of each sample in the section was then adjusted by subtracting the declination of the section mean direction. This is equivalent to setting the mean declination of each core segment to an arbitrary common value, in this case the present geographic north. The mutual consistency of the inclinations and declinations within well defined stratigraphic intervals indicates that little or no distortion had been introduced within a core section by possible twisting of the core. It also justifies this method of increasing the amount of usable magnetostratigraphic information from Hole 521A. The adjusted declinations were used in conjunction with the corresponding inclinations to compute the relative latitude of the virtual geomagnetic pole (VGP). The magnetic polarity stratigraphy was interpreted from the stratigraphic variation of VGP latitude (Fig. 7).

COMPARISON WITH HOLE 521 AND OCEANIC REVERSAL SEQUENCE

Shipboard nannofossil identifications made on core-catcher samples provide a broad biostratigraphic framework for the magnetostratigraphy. In addition, the nannofossils in the sediment from 46.8 to 54.7 m sub-bottom at Hole 521A were zoned by K. Perch-Nielsen (this vol.). The results confirmed the shipboard dates for this hole, except that the core-catcher sample from Core 12 was reassigned to Zone NN8; Zones NN9 and NN10 are found higher in Core 12. Comparison of the paleontological dates for Hole 521 below 60 m sub-bottom and
HOLE 521A LATE MIocene MAGNETic STRATIGraphy

Figure 4. Variation of magnetic susceptibility (K) following different stages of incremental heating of thermally demagnetized pilot samples. Susceptibility gently increases with progressive heating, but there is no sudden change that would be indicative of a massive modification of the magnetic mineralogy within the range of heating.

Figure 5. Examples of thermal cleaning following AF cleaning to (A) 20 mT peak field (Sample 521A-9-2, 49 cm; $M_r = 3.62E - 3$ Am$^{-1}$) and (B) 60 mT peak field (Sample 521A-14,CC (23 cm); $M_r = 1.61E - 2$ Am$^{-1}$). Numbers in the scales in the right-hand plots identify the peak field or temperature. In most samples studied, the final thermal treatment resulted in improved magnetic cleaning.

Hole 521A below 45 m sub-bottom shows good agreement; above these levels different ages are associated with the sediments at comparable depths below the seafloor.

The magnetic polarity zonation of Hole 521A was compared with the magnetic stratigraphy obtained in shipboard studies (Tauxe et al, this vol.) for Hole 521 (Fig. 8). Although the two drilling sites are very close to each other, their magnetic stratigraphies do not agree well.

The magnetic time scale of Lowrie and Alvarez (1981) has been used to compare the Hole 521A magnetic stratigraphy with the record of magnetic field polarity interpreted from oceanic magnetic anomalies. The differences between this time scale and the Ness et al. (1980) and Labrecque et al. (1977) time scales are very small in the Neogene. For example, they predict ages of 16.21, 15.96, and 15.72 m.y., respectively, for the younger reversal boundary of Anomaly 5C.

The clearly positive polarity of the deepest sediments at Hole 521A can probably be associated with the normal polarity of the magnetic field at the time of formation of Anomaly 5C, on which this site was drilled. The basal sediments correspond in age to nannofossil zone NN4. The overlying, well-defined negative magnetozone from about 61.5 m to 68 m sub-bottom can probably be
Figure 6. Stratigraphic plots of the inclination, magnetic susceptibility, and intensity of natural remanent magnetization (NRM) at Hole 521A. Number of samples: 324. A roughly defined sequence of magnetic polarity zones can be detected even though the samples are uncleaned. The similarity between the changes in magnetic susceptibility and NRM intensity shows the effects of lithologic fluctuations.

Short magnetozones of normal and reversed polarity occur from 51.5 m to 61.5 m sub-bottom, interspersed with apparent "polarity zones" that are unfortunately represented only by single specimens and that therefore cannot be trusted. However, a broad, well-defined normal magnetozone from 48.3 m to 51.4 m sub-bottom can probably be correlated with Anomaly 5. The nannofossils from these depths correspond to Zones NN8/NN9, and the base of the magnetozone is associated with Zones NN6/NN7. These correlations disagree with the results of Ryan et al. (1974), who associated Anomaly 5 with the younger nannofossil zones NN10/NN11.

Only a few samples were obtained from sub-bottom depths of 41 to 47 m because of poor core recovery; the samples have normal polarity but are too few to help the magnetic stratigraphy. The samples from 34 to 41 m sub-bottom are dominantly of reversed magnetic polarity.

**DISCUSSION**

The ages associated with magnetic reversal boundaries from Anomaly 5 to Anomaly 5C in the magnetic time scale of Lowrie and Alvarez (1981) have been used to determine ages for the corresponding magnetozones in Hole 521A. The sedimentation rates between these tie-levels have then been computed. For the interval from 48 to 61 m sub-bottom the effective sedimentation rate is fairly constant at around 2.0 m/m.y. This is a very low rate, even for pelagic sediments. Only in the deepest part of Hole 521A, between about 61 m sub-bottom and the bottom of the hole at about 71 m sub-bottom, is the sedimentation rate appreciably higher.
HOLE 521A LATE MIocene MAGNETIC STRATIGRAPHY

Figure 7. Stratigraphic variations of the inclination and relative declination (defined by subtracting the mean declination of each core section from individual declinations in the section) at Hole 521A. The latitude of the virtual geomagnetic pole (VGP) was then computed as a guide in developing the magnetic polarity zonation for this hole.

The combined effects of dissolution and low (and possibly variable) sedimentation rate spoil the magnetic stratigraphy in the cores and make the identification of individual polarity zones or sequences difficult. The magnetic polarity zonation of the sediments can only be correlated in a broad way to the late Miocene oceanic magnetic anomaly polarity record. The identification of the polarity zones corresponding to oceanic magnetic Anomalies 5 and 5C is, however, reasonable. We have tentatively associated Anomaly 5B with the magneto-zones overlying the negative magnetozone younger than Anomaly 5C; the interpretation of Anomaly 5A is more speculative (Fig. 8).
